This report was submitted by The Aerospace Corporation, El Segundo, CA 90245, under Contract F04701-77-C-0078 with the Space and Missile Systems Organization, Deputy for Advanced Space Programs, P. O. Box 92960, Worldway Postal Center, Los Angeles, CA 90009. It was reviewed and approved for The Aerospace Corporation by W. R. Warren, Jr., Director, Aerophysics Laboratory. Lieutenant Arturo G. Fernandez, SAMSO/YCPT, was the project officer for Advanced Space Systems.

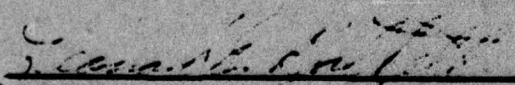

This report has been reviewed by the Information Office (OI) and is releasable to the National Technical Information Service (NTIS). At NTIS, it will be available to the general public, including foreign nations.

This technical report has been reviewed and is approved for publication. Publication of this report does not constitute Air Force approval of the report's findings or conclusions. It is published only for the exchange and stimulation of ideas.

## PREFACE

We are pleased to thank S. N. Suchard and R. W. F. Gross for their continuing interest in and encouragement of this project. We would also like to acknowledge AFWL personnel Colonel Brabson, Major D. Olson, Dr. MacKnight Dr. Hadley, and their collaborators for their many suggestions. Several conversations with Professor G. Glass, Rice University, were of particular value.

Many thanks are due M. A. Kwok for the loan of equipment and help with testing the intrinsic Ge detector. The cw photolysis apparatus was designed by R. W. F. Gross. The O<sub>3</sub> generator was loaned by Professor C. Wittig, University of Southern California. K. L. Foster performed the NEST calculations and wrote the PDP-11 computer program for reducing the experimental data.

## I. INTRODUCTION

In 1964, J. V. V. Kasper, then a graduate student in G. C. Pimentel's laboratory, discovered the first photochemical laser.<sup>1</sup> This laser operated on the spin-orbit transition of the iodine atom at 1.315  $\mu\text{m}$ . The photochemical I-atom laser has been extensively developed by researchers outside of the U.S.<sup>2</sup> and can presently deliver pulse energies of  $\sim 10^3$  J and pulse powers  $> 10^{12}$  W.<sup>3</sup> Since the I atom has a relatively small coefficient of stimulated emission ( $3 \times 10^{-19} \text{ cm}^2$  at  $P_{\text{Ar}} = 1 \text{ atm}$ )<sup>3</sup>, large amounts of energy can be stored in a single laser device, making the I-atom laser attractive as a laser fusion device.<sup>3</sup>

For different applications, a cw I-atom laser would be attractive if it could be produced by chemical reaction or by an efficient energy-transfer scheme. The unsuccessful attempts to produce a population inversion in iodine with chemical reactions (e.g.,  $\text{O} + \text{HI}$ ) are not discussed in this report. Instead, the discussion concerns the most promising energy-transfer system presently known, i.e., the transfer of electronic energy from  $\text{O}_2(^1\Delta)$  to  $\text{I}(^2\text{P}_{3/2})$ .

In 1966, Arnold, Finlayson, and Ogryzlo<sup>4</sup> observed that when  $\text{I}_2$  was added to a gas stream containing  $\text{O}_2(a^1\Delta_g)$  and  $\text{O}_2(b^1\Sigma_g^+)$ , a bright yellow flame appeared. This radiation was easily shown to be  $\text{I}_2\text{B}^3\Pi_{\text{O}_u} + \rightarrow \text{X}^1\Sigma_g^+$  emission. In addition, a strong line appeared at 1.315  $\mu\text{m}$ , which could only be the I-atom transition,  $^2\text{P}_{1/2} \rightarrow ^2\text{P}_{3/2}$ . These authors postulated a mechanism for the dissociation of  $\text{I}_2$ , the behavior of  $\text{O}_2(^1\Sigma)$ , and the excitation of  $\text{I}^*$ , which later work has verified. First, the  $\text{I}_2$  must be dissociated:<sup>†</sup>

<sup>†</sup>The numbering of rate coefficients corresponds to the complete model in Appendix A.

Second, I atoms must be excited to  $I^*$ :

Third, the  $O_2(^1\Sigma)$  must increase rather than decrease, as one would expect from Process (1). This increase in  $O_2(^1\Sigma)$  occurs through Process (3):

Fourth, the yellow emission must be explained. Arnold et al.<sup>4</sup> favored the three-body recombination of I and  $I^*$ :

Derwent, Kearns, and Thrush<sup>5</sup> studied this system in much more detail, however, and established a more complicated mechanism for producing  $I_2(B)$  (Figure 1):

In a series of papers, Derwent and Thrush<sup>6-9</sup> evaluated the rate coefficients for most of the critical chemical processes in this system (Appendix A).

Figure 1. Electronic Energy Levels in  $\text{O}_2\text{-I}_2$  System

They also made the first formal proposal<sup>7</sup> that energy transfer between  $O_2(^1\Delta)$  and I atoms, Process (2), could be used to maintain a cw inversion in the iodine atom. Since that time, several detailed systems studies have been made in order to evaluate the potential of such a transfer laser.<sup>10, 11</sup> The conditions that an  $O_2(^1\Delta)$  pump must satisfy can be determined easily. The equilibrium constant for Process (2) is given by

$$K_{EQ} = \frac{k_1}{k_5} = \frac{[O_2(^3\Sigma_g^-)][I^*]}{[O_2(^1\Delta_g)][I]} = \frac{Q_{rot}(^3\Sigma)g_3g_{I^*}}{Q_{rot}(^1\Delta)g_1g_I} \cdot \exp(-\Delta E/kT) \quad (7)$$

where  $Q$  is the rotational partition function and  $g$  is the electronic degeneracy. The electronic degeneracies involved are  $O_2(^1\Delta):O_2(^3\Sigma):I^*:I = 2:3:2:4$ . The rotational partition functions are nearly identical so that  $K_{EQ} = 2.88^\dagger$  at  $T = 295$  K. The inversion condition (equal population per degeneracy) for the I-atom laser is

$$\frac{[I^*]}{[I]} \geq 0.5 \quad (8)$$

Therefore, the steady-state  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratio necessary to maintain this inversion can be calculated:

$$\frac{[O_2(^1\Delta)]}{[O_2(^3\Sigma)]} = \left(\frac{[I^*]}{[I]}\right) \cdot K_{EQ}^{-1} = 0.174 \quad (9)$$

The conditions necessary to produce a cw energy transfer iodine laser based on  $O_2(^1\Delta)$  can be summarized as follows:

1. An  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratio greater than 0.174 must be obtained.

<sup>†</sup>Derwent and Thrush uniformly quote the value 2.94, although in one paper it is for  $T = 295$  K and in another  $T = 298$  K.

2. The equilibrium given by Process (2) must be rapidly attained, and side reactions must be relatively unimportant.
3. The  $[O_2(^1\Sigma)]$  must be sufficient to dissociate the  $I_2$  that is injected as an I-atom source.
4. A sufficient inversion density on the iodine atom transition must be obtained to overcome cavity losses.

Although most of the data in this report were obtained during FY 76, under contract to AFWL, preliminary studies performed under DARPA sponsorship are included to provide a more complete picture of this transfer system.

## II. SUMMARY

The kinetic model described in the Introduction, and more completely in Appendix A, strongly indicates that a cw I-atom laser, based on energy transfer from  $O_2(^1\Delta)$ , can be constructed. Since the kinetic studies cited earlier<sup>5-9</sup> did not employ large  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratios, no one had demonstrated that  $I^*/I$  ratios  $> 0.5$  could be observed in the laboratory. The present study has shown that, within limits, the relationship given in Eq. (9) is obeyed and that  $I^*/I$  ratios  $> 0.5$  can be achieved in a continuous flow system. Thus, there appears to be no fundamental barrier to the construction of a cw I-atom laser.

The following, obtained under the present contract with AFWL, are significant factors in the attempt to scale the inversion density in the iodine system:

1. Characterization of the absolute densities of  $O_2(^1\Delta)$  and  $O_2(^1\Sigma)$  produced by a single 100-W microwave discharge in  $O_2$ .
2. The development of low-temperature ozone photolysis (LTOP) as a method of producing large  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratios.
3. The determination of the absolute densities of  $I^*$  and  $I$  in the  $O_2-I_2$  system.
4. The effect of wall coatings on the deactivation of electronically excited  $O_2$  and on I-atom recombination.
5. The role of  $O_2(^1\Sigma)$  and possibly  $O(^3P)$  in the dissociation of  $I_2$  and identification of scaling problems.

The highest  $I^*/I$  ratio measured in the LTOP +  $I_2$  experiments was 0.79 with an inversion density ( $[I^*] - 1/2 [I]$ ) of  $3.8 \times 10^{11}/\text{cm}^3$ . The inversion density required for 10% gain/m is  $\sim 1.65 \times 10^{13}/\text{cm}^3$ .<sup>12, 13</sup>

### III. EXPERIMENTAL

#### A. FLOW SYSTEM

The flow system was constructed almost entirely of quartz and pyrex with greaseless glass stopcocks used for valving. Vacuum connections were made with either O-ring seals (pyrex pipe) or deKhotinsky cement (ground-glass joints). Even in high-pressure gas lines, material such as tygon and polyflo tubing was avoided in favor of stainless steel and glass. A large liquid N<sub>2</sub>-cooled glass trap separated the flow system from the core pumping system (a 900-cfm Stokes pump and Roots blower combination). The flow system has an untrapped static leak rate of ~2 mTorr/hr.

In general, an attempt was made to use extremely high purity gases. Most of the quenching rates in the O<sub>2</sub>-I<sub>2</sub> system are small; however, the flow velocities used were also very small ( $\leq 400$  cm/sec). The [O<sub>2</sub>(<sup>1</sup>Σ)] is demonstrably sensitive to gas purity under these experimental conditions. For N<sub>2</sub> (Matheson, 99.995%) and O<sub>2</sub> (Matheson, 99.99%), high purity two-stage regulators were used. The gases were further purified by passing them at 1 atm through molecular sieves traps (Linde 5A), which were periodically baked-out under vacuum at elevated temperatures. Originally, these traps were cooled to -195 K; however, this procedure was found to have little effect on gas purity. SF<sub>6</sub> (Matheson, 99.99%) was used without further purification, although its addition decreased the [O<sub>2</sub>(<sup>1</sup>Σ)] to a greater extent than the published rate coefficients had indicated.<sup>14</sup> Helium (Air Products, 99.99%) was further purified by passing the gas at 1 atm through molecular sieves, which had been baked-out under vacuum and then cooled to 77 K. Molecular I<sub>2</sub> was distilled in vacuo into a glass-bead packed vessel. This vessel was then filled with He at 17 psia (880 Torr), forming a mixture with an I<sub>2</sub> mole fraction of  $3.1 \times 10^{-4}$  at T = 295 K.<sup>15</sup> HI (Matheson, Inc, 98%) was found to be highly contaminated with H<sub>2</sub>. Samples were distilled into a 5-liter flask with a cold finger held at 77 K, subjected to several

freeze-pump-thaw cycles, and diluted with high purity Ar to a total pressure of  $\sim 900$  Torr. Ozone was generated by passing purified  $O_2$  at  $\sim 18$  psia through a high-voltage ac discharge. Originally, a homemade generator was employed. Much higher production rates were later obtained by using a commercial  $O_3$  generator (Ozone Research Corp., Model 03V9-0).<sup>†</sup> The  $O_3 + O_2$  products of the ozonizer flowed at 1-atm pressure through a Si gel trap held at 195 to 200 K. At this temperature,  $O_3$  is adsorbed preferentially on the gel well above its boiling point, thus avoiding the detonation problems often encountered during  $O_3$  liquifaction.<sup>16</sup> After a substantial amount of  $O_3$  was collected (several grams in later experiments), the trap was pumped for several minutes to remove  $O_2$ . Nonindicating Si gel must be used, since the  $O_3$  itself is a deep purple color. If care is exercised, the  $O_3$  removed from the Si gel is  $> 90\%$  pure, the residual being  $O_2$ . The  $O_3$  is carried into the system by flowing  $N_2$  through the trap. The concentration of  $O_3$  is measured in situ by attenuation of 2537 Å radiation. A 10-cm cell provides good sensitivity over the 0.01 to 1.0 Torr pressure range ( $\epsilon_e^{2537} = 0.35 \text{ cm}^{-1} \text{ Torr}^{-1}$ ).<sup>17</sup>

The molar flow rates of  $N_2$ ,  $O_2$ ,  $SF_6$ ,  $H_2$ , and He were measured with rotating ball flowmeters (Matheson) held at constant pressure by low-pressure regulators (Matheson). These flowmeters were calibrated by pressure rise measurements in a standard volume. The molar flow rates of He + HI and He +  $I_2$  mixtures in the atomic resonance fluorescence measurements were measured by timing the pressure drop in calibrated 5-liter storage bulbs.

During these experiments, the following species were directly observed:  $O_2(^1\Delta)$ ,  $O_2(^1\Sigma)$ ,  $I(^2P_{1/2})$ ,  $I(^2P_{3/2})$ ,  $I_2(^3\Pi_{O_u}^+)$ , and  $O_3$ . The following species concentrations were calculated from their molar flow rates:  $O_2$ ,  $N_2$ ,  $SF_6$ , and  $I_2(+ \text{He})$ . Measuring the absolute concentration of the upper and lower levels of a laser transition is clearly less satisfactory than a gain measurement; therefore, the experimental methods and the assumptions made will be dealt with in some detail.

<sup>†</sup> Kindly made available by Dr. Curt Wittig, Department of Electrical Engineering, University of Southern California.

The apparatus has evolved during experimentation; however, two distinct sections can be identified. Section 1 includes the ozone photolysis reactor, a small-diameter section compatible with a 100-W Evenson-type microwave cavity, a HgO-coated section for recombining O atoms,<sup>18</sup> and a movable isothermal calorimeter probe<sup>19,20</sup> for measuring  $O_2(^1\Delta)$ . Figure 2 is a schematic of this section, and Figure 3 is a photograph. Section 2 includes a kinetic flow tube and the associated spectroscopic diagnostics used to measure the species. Figure 4 is a schematic of all the diagnostics.

## B. ISOTHERMAL CALORIMETRY

### 1. THEORY

This technique was originally used by Elias, Ogryzlo, and Schiff for  $O_2(^1\Delta)$ .<sup>19</sup> It has been refined for other studies by Kaufman and coworkers.<sup>20</sup> Bott and Heidner<sup>21</sup> used the technique for recent measurements of H-atom quenching of vibrationally excited hydrogen halides.

Briefly, the method works as follows: a coil of 0.010-in. Ni wire forms one arm of a Kelvin bridge circuit. This coil of wire is inserted into the gas stream and heated by an external power supply to an elevated temperature. At a temperature  $T$  ( $\sim 150^\circ\text{C}$ ), the coil resistance is such that the bridge is balanced (Figure 5). The circuit design for the self-balancing bridge was taken from the work of Ham et al.<sup>20</sup> Thus, with no active species in the gas stream, the power dissipation of the coil is

$$W_{\text{coil}}(1) = i_{\text{coil}}^2(1) \cdot R_{\text{coil}} = i_{\text{coil}}^2(1) \cdot R_s \quad (10)$$

When an active species in the gas stream can impart energy to the coil, the external circuit supplies only a fraction of the power necessary to heat the coil to the temperature  $T$ . The external circuit now supplies

$$W_{\text{coil}}(2) = i_{\text{coil}}^2(2) \cdot R_{\text{coil}} = i_{\text{coil}}^2(2) \cdot R_s \quad (11)$$

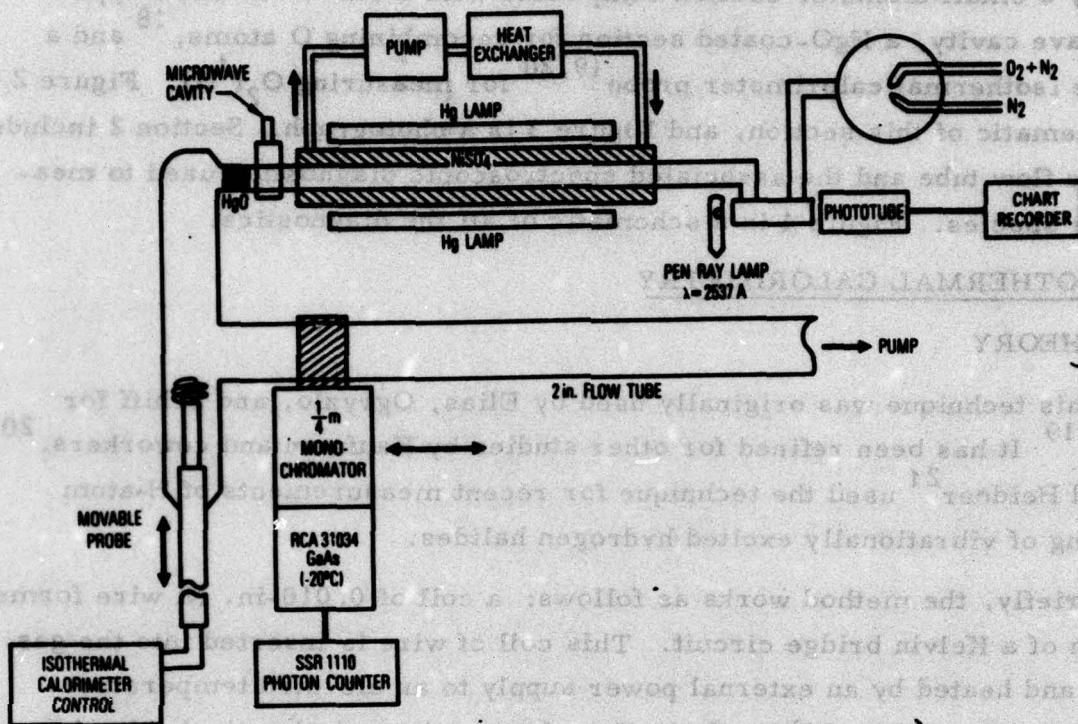

Figure 2. Continuous Photolysis Flow Tube

Figure 3. Low-Temperature Continuous-Photolysis Flow Tube and  $O_2^*$  Diagnostics. (a) Isothermal Calorimeter Probe. (b) Monochromator on Movable Platform. (c) Cooled GaAs Photomultiplier, Pulse Height Amplifier-Discriminator and Photon Counter. (d) Low-Temperature CW Photolysis Apparatus. (e) In Situ  $O_3$  Diagnostic (2537-Å Lamp, 10-cm Absorption Cell, Photomultiplier). (f) Microwave Discharge Region and HgO Surface for O-Atom Recombination.

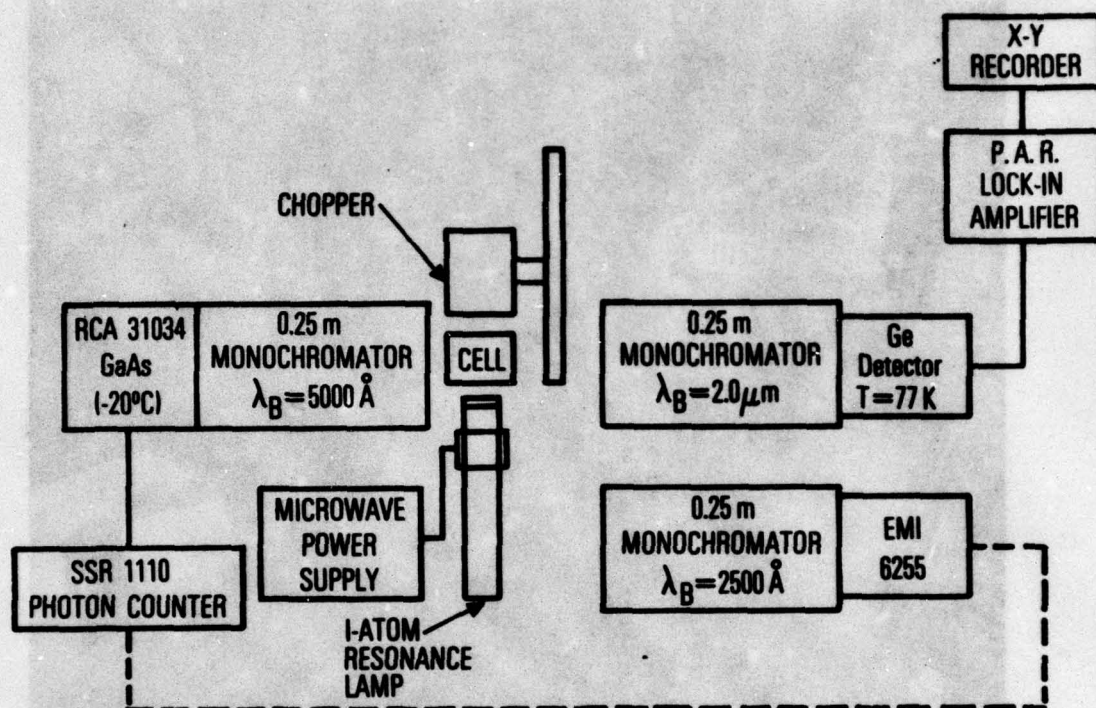

Figure 4. Diagnostics for  $O_2(^1\Delta)$ -I Atom Transfer System

Thus, the power supplied by the active species is the difference between these two power readings

$$\Delta W = W_{\text{coil}(1)} - W_{\text{coil}(2)} = i_{\text{coil}(1)}^2 - i_{\text{coil}(2)}^2 \cdot R_s \quad (12)$$

When the active species is  $\text{O}_2(^1\Delta)$ ,  $\Delta H = 9.5 \times 10^4 \text{ J/mole}$  (22.7 kcal/mole) is imparted for each mole of  $\text{O}_2(^1\Delta)$  deactivated on the coil surface. Since the coil measures power (J/sec), the probe measures the molar flow rate of  $\text{O}_2(^1\Delta)$  (moles/sec) rather than the concentration. The latter is easily determined by the relationship

$$\dot{m}_{1\Delta} = \frac{\Delta W}{\Delta H} \quad (13)$$

$$P_{1\Delta} = \left( \frac{\dot{m}_{1\Delta}}{\sum_i \dot{m}_i} \right) \cdot P_{\text{total}} \quad (14)$$

## 2. LIMITATIONS

The application of isothermal calorimetry to measuring  $\text{O}_2(^1\Delta)$  is not quite as simple as outlined. The following questions must be addressed:

1. Does the probe remove 100% of the  $\text{O}_2(^1\Delta)$ ?
2. Are there other energetic species in the gas stream that will be recorded by the probe?
3. When  $\text{O}_2(^1\Delta)$  is deactivated on the probe, does some of the energy escape to the gas phase?

Although the probe is not 100% efficient in deactivating  $\text{O}_2(^1\Delta)$ , the fraction of  $^1\Delta$  removed by the probe can be determined by noting the decrease in the 1.27- $\mu\text{m}$  fundamental emission (or the 6340- $\text{\AA}$  "dimol" emission) when the probe is inserted in the gas stream. The technique is illustrated in Figure 6. For example, if the signal at 1.27  $\mu\text{m}$ , S, is monitored, the signals downstream and upstream of the probe can be ratioed to give

**Figure 6. Isothermal Calorimetric Probe Efficiency Measurement**

$$\frac{S_2}{S_1} = \frac{C[O_2(^1\Delta)]_f}{C[O_2(^1\Delta)]_i} \quad (15)$$

The probe efficiency,  $E$ , then is given by

$$E = \left\{ 1 - \frac{[O_2(^1\Delta)]_f}{[O_2(^1\Delta)]_i} \right\} = \left( 1 - \frac{S_2}{S_1} \right) \quad (16)$$

Therefore, Eq. (13) must be modified to read

$$\dot{m}_{1\Delta} = \frac{\Delta W}{E \cdot \Delta H} \quad (17)$$

We are fortunate in this experiment in being quite certain that the energy content of minority constituents such as O atoms and  $O_2(^1\Sigma)$  is small compared with the energy content of  $O_2(^1\Delta)$ . Thus, the measured probe signal is due entirely to the deactivation of  $O_2(^1\Delta)$ . It is not known positively that all of the energy appears as probe signal when an  $O_2(^1\Delta)$  molecule is deactivated. When H atoms recombine on a probe, it is known that the  $H_2$  formed is not vibrationally excited.<sup>20,22</sup> Expressed in different language, all the recombination energy appears on the probe or the "accommodation coefficient" for the energy is unity. If the accommodation coefficient should turn out to be  $< 1$ , the  $[O_2(^1\Delta)]$  in this study will have been underestimated, which is the preferable direction of error.

### C. SPECTROSCOPY

The relevant spectroscopy of the  $O_2$  and  $I_2$  systems is summarized in Table I. Methods previously used to absolutely calibrate emission intensities include blackbody calibration, absolute radiance of the NO + O chemiluminescence,<sup>23</sup> ESR measurements on the excited state,<sup>24</sup> and measurement of

the excited-state density with isothermal calorimetry.<sup>19,25</sup> The present work has utilized isothermal calorimetry to measure the  $O_2(^1\Delta)$ ; both the 1.27- $\mu\text{m}$  fundamental emission and the 6340- $\text{\AA}$  "dimol" emission have been calibrated against the calorimetric probe.

## 1. $O_2(^1\Delta)$ EMISSION FEATURES

Ogryzlo and coworkers<sup>25,26</sup> identified the broad emission band at 6340  $\text{\AA}$  as a cooperative emission of a single photon by two  $O_2(^1\Delta)$  molecules

Derwent and Thrush<sup>6</sup> measured the radiative collision rate coefficient,  $k_r$ , to be  $16 \pm 4 \text{ cm}^3/\text{mol-sec}$ . The emission intensity should depend on  $[O_2(^1\Delta)]^2$ , whereas the fundamental emission at 1.27  $\mu\text{m}$  obviously depends on  $[O_2(^1\Delta)]$ . Figure 7 is a plot of  $I_{6340}$  versus  $(\dot{m}_1)^2$ . The detection system for 6340  $\text{\AA}$  was highly stable over long periods of time, so that the absolute concentration of  $O_2(^1\Delta)$  was determined on a day-to-day basis by this emission intensity. The Ge detector used to measure the  $^1\Delta \rightarrow ^3\Sigma$  emission at 1.27  $\mu\text{m}$  and the  $I^* \rightarrow I$  emission at 1.315  $\mu\text{m}$  does not have good long-term stability. For this reason,  $I_{1.27}$  was calibrated against  $I_{6340}$  for each run.

## 2. $O_2(^1\Sigma)$ EMISSION

The  $^1\Sigma \rightarrow ^3\Sigma$  emission at 7619  $\text{\AA}$  "dimol" emission. The concentrations of  $O_2(^1\Delta)$  and  $O_2(^1\Sigma)$  can be seen to be interrelated by the following equation:

$$\frac{[O_2(^1\Sigma)]}{[O_2(^1\Delta)]^2} = \frac{k_r}{A_{1\Sigma}} \left( \frac{R_{6340}}{R_{7619}} \right) \left( \frac{I_{7619}}{I_{6340}} \right) \quad (19)$$

The values for  $A_{1\Sigma}$  and  $k_r$  are given in Table I. In the absence of  $I_2$ , the  $O_2(^1\Sigma)$  is formed by energy pooling of  $O_2(^1\Delta)$

Figure 7 is a plot of  $I_{7619}$  versus  $m_{1\Delta}^2$ , confirming that this relationship holds in the present system.

### 3. $\text{I}(^2\text{P}_{1/2})$ EMISSION

The absolute calibration of  $\text{I}^*$  unfortunately is dependent upon knowing the radiative lifetime ratio of  $\text{I}(^2\text{P}_{1/2})/\text{O}_2(^1\Delta)$ . The situation is therefore similar to that just described for  $\text{O}_2(^1\Sigma)$ . In the present case, the  $[\text{I}^*]$  is determined as follows:

$$\frac{[\text{I}(^2\text{P}_{1/2})]}{[\text{O}_2(^1\Delta)]} = \frac{A_{1\Delta} I_{1.315}}{A_{\text{I}^*} I_{1.27}} \cdot \left( \frac{R_{1.27}}{R_{1.315}} \right) \quad (21)$$

The indicated calibration is made with the Ge detector. The relative response correction is quite small between these two wavelengths. Neither the  $\text{O}_2(^1\Delta)$  nor the  $\text{I}(^2\text{P}_{1/2})$  radiative lifetimes is known with a high degree of accuracy, although reasonably good evidence supports 3660 sec for  $\text{O}_2(^1\Delta)$ <sup>27</sup> and 0.13 sec for  $\text{I}^*$ .<sup>30</sup> Throughout this study, the assumed value of  $A_{1\Delta}/A_{\text{I}^*} = 3.3 \times 10^{-5}$  was scrutinized for internal consistency with the experimental data.

### 4. $\text{I}(^2\text{P}_{3/2})$ RESONANCE FLUORESCENCE

The reaction of HI with excess H atoms was used to generate a known concentration of ground-state iodine atoms:

Even if some of the I atoms recombine to  $\text{I}_2$ , the reaction

Figure 7. Calibration of 6340-Å "Dimol" Emission and 7619-Å  $\text{O}_2(^1\Sigma)$  Emission Versus  $(m_1)_\Delta^2$

(23)

followed by Reaction (22), regenerates them. This titration reaction was used to calibrate atomic resonance fluorescence on the 1830-Å line terminating on  $\text{I}(^2\text{P}_{3/2})$  (Table I). Figure 8 is a plot of the resonance fluorescence intensity versus  $[\text{I}(^2\text{P}_{3/2})] = [\text{HI}]_{\text{added}}$  and  $I_{1830\text{Å}}$  versus  $[\text{I}(^2\text{P}_{3/2})] = 2 \cdot [\text{I}_2]_{\text{added}}$ . Since  $\text{I}_2$  must be carried in with a diluent gas from a saturator at a known temperature, this plot demonstrates that a well-designed  $\text{I}_2$  saturator does allow one to accurately add  $\text{I}_2$  to a flow system.

#### 5. $\text{I}_2$ EMISSION

A relative measurement of the  $[\text{I}_2]$  in the  $\text{O}_2$ - $\text{I}_2$  system is the intensity of  $\text{I}_2(\text{B} \rightarrow \text{X})$  emission, which has a spectral maximum at 5800 Å.<sup>8</sup> This emission provides the yellow flame observed around the  $\text{I}_2$  injector. Since the B → X emission is also proportional to  $[\text{O}_2(^1\Sigma)] \cdot [\text{O}_2(^1\Delta)]$ ,<sup>8</sup> only qualitative conclusions can be drawn about the  $[\text{I}_2]$  in the system.

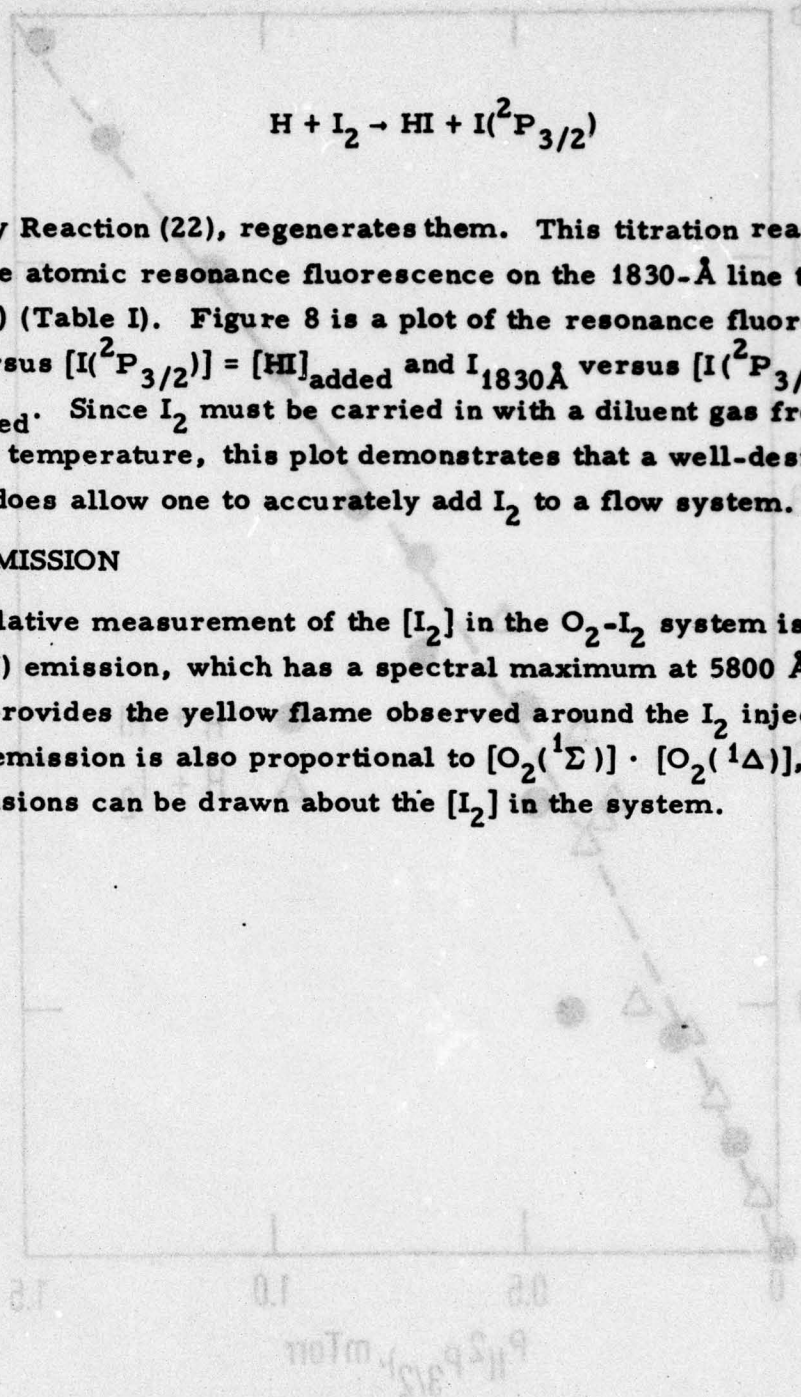

Figure 8. Calibration of Atomic Resonance Fluorescence from  $\text{I}(^2\text{P}_{3/2})$

#### IV. THEORY OF LOW-TEMPERATURE O<sub>3</sub> PHOTOLYSIS AS SOURCE OF O<sub>2</sub>(<sup>1</sup>Δ) AND O<sub>2</sub>(<sup>1</sup>Σ)

The photolysis of O<sub>3</sub> was reviewed recently by Lissi and Heicklen.<sup>31</sup> For the case of weak photolysis at low O<sub>3</sub>/N<sub>2</sub> ratios, the following mechanism gives a limiting quantum yield of 4 (O<sub>3</sub> molecules destroyed per quantum absorbed):

This phenomenon might be termed a kinetics-dominated regime, because of the low intensity of photolysis radiation. Large initial concentrations of O<sub>2</sub>(<sup>1</sup>Δ) and O(<sup>1</sup>D) can be made from the flash photolysis of O<sub>3</sub>.<sup>32</sup> During the flash, photolysis dominates the kinetics to a large extent. If the intensity of the flash is such that all the O<sub>3</sub> is removed before kinetics occur, Reactions (25) and (27) are not important. The same criteria also apply to a high-intensity continuous photolysis source. When these criteria are met, the O(<sup>3</sup>P) atoms formed in Process (26) are forced to recombine, presumably to ground-state molecular oxygen

The quantum yield of  $O_3$  photolysis is then 1.0, and the  $[O_2(^1\Delta)]/[O_2(^3\Sigma)] = 2.0$ .

Continuous photolysis sources are not generally able to dominate the  $O_3$  system kinetics. The  $O(^3P)$  and  $O_2(^1\Delta)$  compete for the  $O_3$  against the photolysis process. Kurylo et al.<sup>33</sup> measured  $k_{25} = 4.5 \times 10^{-11} \exp(-5620/RT)$ , whereas Davis et al.<sup>34</sup> measured  $k_{27} = 2.0 \pm 0.2 \times 10^{-11} \exp(-4522 \pm 210/RT)$ . These two rate coefficients were used to calculate the temperature-dependent first-order destruction rate of  $O_3$  by 1 Torr of  $O(^3P)$  atoms and 1 Torr of  $O_2(^1\Delta)$  (Table II). These numbers qualitatively indicate the magnitude of the photolysis rate ( $\text{sec}^{-1}$ ) necessary to produce 1 Torr of  $O_2(^1\Delta)$  in a cw system without producing excessive  $O_2(^3\Sigma)$ . The advantage of photolyzing  $O_3$  at low temperatures is immediately clear. Whether low-temperature operation is or is not a necessity depends upon the photolysis rate.

$O_3$  is especially advantageous as a photolytic precursor for  $O_2(^1\Delta)$  because it has a large photon absorption cross section in the ultraviolet ( $\sigma = 1 \times 10^{-17} \text{ cm}^2$  at  $2500 \text{ \AA}$ )<sup>17</sup> and a large quantum efficiency ( $> 0.95$ )<sup>35</sup> for the production of  $O_2(^1\Delta)$ . Our initial photolysis reactor had two Hanovia LL 189A lamps positioned parallel to the photolysis vessel within a MgO-coated elliptical reflector. Approximately 500 W of ultraviolet radiation is emitted by these lamps in sixteen lines falling within the Hartley band of  $O_3$  (200 nm to 320 nm). The final photolysis reactor, which permitted photolysis down to  $\sim 200 \text{ K}$ , had four of the Hanovia LL 189A lamps positioned around a quadruply concentric quartz reaction vessel. The latter apparatus is shown in Figure 9.

Table II.  $O_3$  Reaction Rates with  $O(^3P)$  and  $O_2(^1\Delta)$  as a Function of Temperature

T, K	$k_{25'}$ $cm^3/sec$	$k_{27'}$ $cm^3/sec$	$K_{25'}$ $sec^{-1}/Torr$	$K_{27'}$ $sec^{-1}/Torr$
340	$1.1 \times 10^{-14}$	$2.5 \times 10^{-14}$	385	875
320	$6.5 \times 10^{-15}$	$1.6 \times 10^{-14}$	228	560
300	$3.6 \times 10^{-15}$	$1.0 \times 10^{-14}$	126	350
280	$1.8 \times 10^{-15}$	$5.9 \times 10^{-15}$	63	207
260	$8.5 \times 10^{-16}$	$3.2 \times 10^{-15}$	29.8	112
240	$3.4 \times 10^{-16}$	$1.5 \times 10^{-15}$	11.9	52.5
220	$1.2 \times 10^{-16}$	$6.4 \times 10^{-16}$	4.2	22.4
200	$3.2 \times 10^{-17}$	$2.3 \times 10^{-16}$	1.1	8.1

Figure 9. Quadruply Concentric, Low-Temperature  $O_3$  Photolysis Vessel

The photolysis rate,  $R(\text{sec}^{-1})$ , can be expressed in terms of the intensity in each line,  $J_i(\text{photons}/\text{cm}^2\text{-sec})$ , and the  $\text{O}_3$  absorption cross section at that line,  $\sigma_i(\text{cm}^2)$ . Thus,<sup>†</sup>

$$R = \sum_i R_i \approx \sum_i J_i \sigma_i \quad (30)$$

In this system,  $R$  was not measured, although it is perfectly feasible to do so.<sup>36</sup> With the Hanovia specification, the known  $\sigma_i$  for  $\text{O}_3$ , and a judicious guess for the coupling efficiency of radiation into the photolysis reactor,  $R = 10 \text{ sec}^{-1}$ . At 300 K, this photolysis rate will not be competitive with kinetics when  $[\text{O}(^3\text{P})]$  and  $[\text{O}_2(^1\Delta)] > 0.02 \text{ Torr}$  (Table II). For the experiments performed to date, optimum conditions were  $[\text{O}_3]_{\text{initial}} \leq 0.015 \text{ Torr}$  and  $[\text{O}_2(^1\Delta)] \approx 0.01 \text{ Torr}$ .

For a fixed transit time through the photolysis reactor, the rate of photolysis must be sufficient to decompose virtually all of the  $\text{O}_3$ , since the remaining  $\text{O}_3$  will react with the  $\text{O}_2(^1\Delta)$ . The photolytic removal of  $\text{O}_3$  can be written:

$$\frac{-d(\text{O}_3)}{dt} = \sum_i \left( \frac{J_i}{L} \right) \left\{ 1 - \exp[-\sigma_i(\text{O}_3)L] \right\} \approx \sum_i J_i \sigma_i(\text{O}_3) = R(\text{O}_3) \quad (31)$$

$$\ln \frac{(\text{O}_3)}{(\text{O}_3)_0} = R t \quad (32)$$

where  $t$  is the transit time of the gas through the photolysis region.

<sup>†</sup> In Eq. 30 and in the following analysis, weak absorption of the photolysis radiation is assumed for the sake of clarity. This assumption means replacing Beer's law by  $I/I_0 \approx 1 - \sigma_i(\text{O}_3)L$ , where  $L$  is the absorption path length. This approximation is valid for all the  $\text{O}_3$  densities used in this study.

If 95% of the  $O_3$  has to be photolyzed, Eq. (32) gives  $t = 3/R$ . With  $R = 10 \text{ sec}^{-1}$  substituted,  $t = 300 \text{ msec}$ . Thus, the residence time in the photolysis vessel must be  $> 300 \text{ msec}$  for complete photolysis, implying a linear flow velocity in the 30-cm-long lamp section of  $30 \text{ cm}/0.3 \text{ sec} = 1 \text{ m/sec}$ . Experimentally, the optimum flow velocity was  $1 \text{ m/sec}$ .

Although these preliminary calculations fit the data to be presented in Section V quite well, further modelling studies were performed using the The Aerospace Corporation NEST computer program.<sup>37</sup> In this way, it is possible to obtain a more quantitative understanding of the variation of  $O_2(^1\Delta)$  with the photolysis rate,  $R$ , the  $[O_3]$ , and with photolysis temperature,  $T$ .

The photolysis system was constrained to be isothermal by the artificial addition of a large amount of nondeactivating diluent. Later experimentation showed that for typical conditions ( $[O_3]/[N_2] \sim 0.02$ ), a temperature rise occurs. Thus, the  $[O_2(^1\Delta)]/[O_2(^3\Sigma)]$  ratio does not increase as rapidly with temperature decrease as the calculations predict. In addition, the  $[O_2(^1\Delta)]$  produced by photolysis is increased by adding  $SF_6$ , presumably because of the large heat capacity of the latter molecule.

Figures 10 and 11 are two NEST runs for reasonable experimental conditions. The first case ( $P_{O_3} = 0.1 \text{ Torr}$  and  $T = 300 \text{ K}$ ) shows that in the absence of other loss processes for  $O_2(^1\Delta)$  (such as wall deactivation on these very slow time scales), an  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratio of  $\sim 0.24$  would be produced. Photolysis of the same gas mixture at  $150 \text{ K}$  is predicted to yield  $O_2(^1\Delta)/O_2(^3\Sigma) = 1.75$ .

Figure 10. NEST<sup>37</sup> Calculation of  $O_2(^1\Delta)/O_2(^3\Sigma)$  Ratio Produced by  $O_3$  Photolysis at  $T = 300$  K. ( $[O_3]^0 = 5.4 \times 10^{-9}$  mole/cm<sup>3</sup>,  $P_{N_2} = 5$  Torr,  $R = 10$  sec<sup>-1</sup>)

## V. RESULTS AND DISCUSSION

### A. QUANTITATIVE MEASUREMENTS OF $O_2(^1\Delta)$ AND $O_2(^1\Sigma)$

#### 1. MICROWAVE DISCHARGE EXPERIMENTS

A rather brief parameter study in the 0.5 to 2.0 Torr  $O_2$  pressure range indicated that earlier results<sup>6</sup> obtained with a single 100-W Evenson-type discharge were substantially correct. Figure 12 demonstrates that  $O_2(^1\Delta)/O_2(^3\Sigma) \approx 0.07$  is typical of most experimental conditions; Figure 13 indicates a power saturation occurring when the microwave discharge power is raised above 50 W; Figure 14 indicates the variation of  $O_2(^1\Delta)/O_2(^3\Sigma)$  with molar flow rate of  $O_2$  at constant pressure. Unfortunately, data were not taken at very low  $O_2$  pressures. Figure 15 shows the very slow decay of  $O_2(^1\Delta)$  on a phosphoric acid ( $H_3PO_4$ ) coated surface. This latter measurement was made because Ogryzlo had indicated that  $H_3PO_4$  was the only surface tested that inhibited I-atom wall recombination. Later, it was learned that Halocarbon wax was far superior to  $H_3PO_4$  in suppressing I-atom recombination. The upstream portion of the flow system is still coated with  $H_3PO_4$  since it is somewhat less efficient than pyrex in deactivating  $O_2(^1\Delta)$ . The best surface coating is one that will not deactivate  $O_2(^1\Sigma)$  or recombine I atoms.

#### 2. $O_3$ PHOTOLYSIS EXPERIMENTS

By means of the photolysis apparatus shown in Figure 2,  $O_3$  was photolyzed in  $N_2$  buffer gas. The initial results (Figure 16) showed that if the  $NiSO_4$  solution filter was allowed to heat up, a substantial decrease in the  $O_2(^1\Delta)$  production was observed between 25 and 40°C. This  $NiSO_4$  solution is in contact with the outer wall of the 19-mm-o.d. photolysis vessel. Some cooling of the photolysis vessel was then achieved by recirculating the  $NiSO_4$  solution through an ice bath. These data are presented as plots of  $L_{7619}$ , which is proportional to  $[O_2(^1\Delta)]^2$ , versus time after the lamps were turned on (Figure 17). The temperature of the photolysis vessel was cycled, and the

at  $T = 300$  to  $315$  K

Figure 17.  $O_2(^1\Delta)$  Production from  $O_3$  Photolysis at  $T = 280$  to  $300 \text{ K}$ ; Variation with Photolysis Lamp Warm-Up Time

data fall roughly along isotherms. Once again, an improved  $O_2(^1\Delta)$  yield at lower temperatures is observed.

The data in Figure 17 indicate that one problem with the present lamp system is that the ultraviolet output varies markedly with time after turn-on. Later experiments showed these lamps to be quite sensitive to their operating temperature ( $\sim 150^\circ\text{C}$ ).

### 3. LOW-TEMPERATURE $O_3$ PHOTOLYSIS EXPERIMENTS

Experiments were then continued in the quadruply concentric photolysis reactor shown in Figure 9. A survey was made of the  $O_2(^1\Delta)$  production efficiency as a function of pressure, temperature, and the mole fractions of  $O_3$ ,  $N_2$ , and  $SF_6$  (the last was added for increased heat capacity). The results are summarized in Table III. These data were taken in early 1975, and the results for  $O_2(^1\Delta)$  production are somewhat superior to those obtained in 1976 during the  $I_2$  mixing experiments. The reason for this difference is unknown, but it may be a result of lamp fatigue over time.

#### B. $O_2(^1\Delta)$ - $I_2$ SYSTEM

##### 1. MODIFIED FLOW SYSTEM

The concentrations of the species are monitored transverse to the flow axis of a 2- by 2-cm quartz flow tube. This tube was internally coated with Halocarbon wax. Iodine in an He carrier was injected axially. Figure 18 is a scale drawing of the flow tube.

For a given set of experimental conditions, all the following data were obtained: the total system pressure,  $P$ ; the appropriate molar flow rates,  $\dot{m}_i$ , read from the calibrated rotamer flowmeters; the  $O_3$  concentration with ultraviolet absorption at  $2537 \text{ \AA}$  (for the photolysis experiments); the  $O_2(^1\Delta)$  "dimol" emission (only in the absence of  $I_2$ ), the  $O_2(^1\Sigma)$  emission; and a spectral scan of the  $1.27\text{-}\mu\text{m}$   $O_2(^1\Delta)$  and  $1.315\text{-}\mu\text{m}$   $I^*$  peaks. A typical near-infrared spectrum is shown in Figure 19.

Figure 18. Flow Tube for  $O_2 + I_2$  Experiments

Figure 19. Typical Spectral Scans of  $1.27\text{-}\mu\text{m}$   $\text{O}_2$  ( $1\Delta$ ) Transition and  $1.315\text{-}\mu\text{m}$  I-Atom Transition

A small data reduction program was written for the Chemical Kinetics Department of the Aerophysics Laboratory PDP-11 computer to reduce these data to absolute concentrations of the relevant system species.

## 2. DATA ACQUISITION AND ANALYSIS

The iodine mixing experiments were performed both for discharge-generated and photolysis-generated  $O_2(^1\Delta)$ . This close comparison of the two  $O_2(^1\Delta)$  generation methods is particularly valuable. First, the  $O_3$  photolysis yields the same final products as the discharge; in the present apparatus,  $O_3$  photolysis yields a higher  $^1\Delta/^3\Sigma$  ratio, however. Thus, if the  $O_3$  photolysis method can produce a population inversion in the I atom, the discharge method can also, if the criterion  $^1\Delta/^3\Sigma > 0.17$  can be met. Second, there is the possibility of a systematic error in determining  $I^*$ . By performing the discharge and the photolysis experiments in the same flow system with  $I_2$  added in identical fashion, the relative  $I^*/I$  ratios produced by the two methods can be predicted confidently.

The systematic error involves the ratio of the radiative lifetimes of  $O_2(^1\Delta)$  and  $I^*$ . The  $[O_2(^1\Delta)]$  is measured by isothermal calorimetry and the  $[O_2(^3\Sigma)]^0$  by a mass flow meter.

$$\dot{m}_{3\Sigma} = \dot{m}_{3\Sigma}^0 - \dot{m}_{1\Delta} \quad (\text{discharge}) \quad (33)$$

$$\dot{m}_{3\Sigma} = \frac{3}{2} \dot{m}_{O_3} - \dot{m}_{1\Delta} \quad (\text{photolysis}) \quad (34)$$

The amount of  $I_2$  added is known (Section III.B.4) and, therefore, with complete dissociation assumed,  $[I^*] + [I] = 2 [I_2]_{\text{added}}$  is known. In order to obtain a complete solution to the problem, either  $[I^*]$  or  $[I]$  must be measured absolutely. Absolute calibration of  $[I^*]$  is extremely difficult. In this study,  $[I]$  was calibrated absolutely by means of atomic resonance fluorescence in

an  $O_2$ -free system, but the technique is awkward to use with  $O_2$  and  $I_2$  present because of the rapidly changing optical transmission of the cell at 1830 Å.

Therefore, there are two choices. The first is to assume the radiative lifetimes of  $O_2(^1\Delta)$  and  $I^*$  are in the correct ratio:

$$\frac{\Phi_{I^*}}{\Phi_{^1\Delta}} = \frac{A_{I^*} [I^*] R_{1.315}}{A_{^1\Delta} [O_2(^1\Delta)] R_{1.27}} \quad (35)$$

where  $\Phi$  is the measured intensity, and  $R$  is the black-body calibrated system response (lens, monochromator, and detector) at the indicated wavelengths. All the quantities are measured in the present experiment except  $[I^*]$  and  $(A_{I^*}/A_{^1\Delta})$ .

Therefore,

$$[I^*] = \left( \frac{\Phi_{I^*}}{\Phi_{^1\Delta}} \right) \left( \frac{A_{^1\Delta}}{A_{I^*}} \right) \left( \frac{R_{1.27}}{R_{1.315}} \right) [O_2(^1\Delta)] \quad (36)$$

can be calculated, where  $(R_{1.27}/R_{1.315}) = 0.854$  in this system, and the accepted value of  $A_{^1\Delta}/A_{I^*} = 3.35 \times 10^{-4}$  (Appendix C).  $[I]$  is then determined by mass balance assuming complete dissociation of  $I_2$ :

$$[I] = 2 [I_2]_{\text{added}} - [I^*] \quad (37)$$

A second evaluation of  $[I^*]$  can be obtained by analyzing Eq.(B-3).

$$\frac{[I^*]}{[I]} = \frac{k_1 [O_2(^1\Delta)]}{(k_5 + k_6) [O_2(^3\Sigma)]} \quad (B-3)$$

If the Derwent-Thrush analysis is correct as the present work also indicates,  $k_6 \ll k_5$ , and the following expression results,

$$[I^*] = K_{EQ} [I] \frac{[O_2(^1\Delta)]}{[O_2(^3\Sigma)]} \quad (38)$$

$$= \frac{2.88(2[I_2]_{\text{added}} - [I^*])[O_2(^1\Delta)]}{[O_2(^3\Sigma)]} \quad (39)$$

By the rearrangement of Eq. (39), the following result is obtained:

$$[I^*] = \frac{5.76 [I_2]_{\text{added}} [O_2(^1\Delta)]}{\left(1 + 2.88 [O_2(^1\Delta)]/[O_2(^3\Sigma)]\right) [O_2(^3\Sigma)]} \quad (40)$$

These two methods of analysis are indeed independent, although each of them has assumptions that should be carefully scrutinized. In fact, Derwent and Thrush<sup>7</sup> calculated  $A_* = 6 \text{ sec}^{-1}$  by comparison of these two methods. The present experiment suggests that  $A_*$  is somewhat larger than the accepted value of  $7.8 \text{ sec}^{-1}$ .<sup>30</sup> Clearly, it is difficult to control all of the important variables in this system.

As will be shown by the data presented in the following sections, both the discharged  $O_2$  and  $O_3$  photolysis systems behave in a well-understood fashion when small amounts of  $I_2$  are added. When larger amounts of  $I_2$  are added, a catastrophic decrease in  $^1\Sigma$  is observed. In this regime,  $O_2(^1\Sigma)$  and  $I^*$  no longer increase linearly with  $I_2$  addition. The explanation would appear to be that the  $I_2$  is no longer completely dissociated. Since in this data analysis it is assumed that  $[I^*] + [I] = 2[I_2]_{\text{added}}$ , the results cannot be valid after this

assumption breaks down. The presence of substantial amounts of  $I_2$  will also be detrimental to the system since

proceeds with a near-gaskinetic rate coefficient. The onset of the  $^1\Sigma$  catastrophe appears to be variable but occurs at  $[^1\Delta] / [I_2]_{\text{added}}$  ratios of  $\sim 50$  to 250 and  $[I_2]_{\text{added}}$  of 0.2 to 0.5 mTorr. In these multiple-diagnostic experiments, the spectroscopic measurements were not made as a function of mixing time of the  $I_2$  with the  $O_2(^1\Delta)$  stream. Therefore, how rapidly (and in what direction) the  $O_2(^1\Sigma)$  and  $[I^*]$  vary with time is not known. This  $^1\Sigma$  catastrophe is semiquantitatively analyzed in the following sections.

### 3. DISCHARGED $O_2$ : BEHAVIOR OF $I^*$ AND $O_2(^1\Sigma)$

The interrelationship between the extent of  $I_2$  dissociation and the absolute  $[O_2(^1\Sigma)]$  must be evaluated. The results of present study confirm the major conclusions of Derwent and Thrush that  $O_2(^1\Sigma)$  is responsible for maintaining the dissociation of  $I_2$  (the initial breakup of  $I_2$  in the LTOP experiments is a separate question).

The  $I_2$  dissociation cycle presented in Figure 20 is an example of a positive feedback loop. Any change in the system brings about an accentuation of that change. For example, if the  $[I^*]$  decreases, the formation of  $O_2(^1\Sigma)$  by  $k_2$  decreases and the dissociation rate of  $I_2$  by  $k_{15}$  decreases, thus decreasing the equilibrium amount of  $[I^*]$  and  $[I]$  still further. If even a small fraction of the  $[I_2]_{\text{added}}$  remains undissociated, the effect of its gaskinetic quenching efficiency on  $I^*$  is a serious problem.

The data to be discussed in this section are shown in Figures 21 through 23. The principal difference in these plots is the  $[O_2(^1\Delta)]$  and  $[O_2(^1\Sigma)]^0$ . Each figure is a plot of Eqs. (B-3) and (B-13).

$$\frac{[I^*]}{[O_2(^1\Delta)]} = \frac{k_1}{(k_5 + k_6)} \frac{[I]}{[O_2(^3\Sigma)]} \quad (B-3)$$

 $(I^* + I)_{\text{max}} = 6 \times 10^{-4} \text{ Torr}; \tau(I_2 \text{ mixing to ob-}$   
 $\text{servation}) = 20 \text{ msec}]$

$$\frac{[O_2(^1\Sigma)] - [O_2(^1\Sigma)]^0}{[O_2(^1\Sigma)]^0} = \frac{k_2 k_1}{k_9(k_5 + k_6)} \frac{[I]}{[O_2(^3\Sigma)]} \quad (B-13)$$

From Eq. (B-3), a value for the equilibrium constant  $K_{EQ} = k_1/k_5 \approx k_1/(k_5 + k_6)$  can be derived. If it is assumed that the  $[I_2]$  is known and that it is completely dissociated, a result is obtained for  $K_{EQ}$  that is systematically in error by  $\sim 28\%$ . Subsequent runs gave  $K_{EQ}$  values that were somewhat smaller; however, they are uniformly high. This observation can be explained by any combination of the following possibilities:

1. More  $I_2$  is being added than the calibration experiments indicate.
2.  $A_{*}$  is too small, Eq. (36).
3.  $A_{1\Delta}^I$  is too large, Eq. (36).

At high  $I_2$  additions, there is an indication of scaling problems. This is particularly clear for the plot of  $[O_2(^1\Sigma)] - [O_2(^1\Sigma)]^0/[O_2(^1\Sigma)]^0$ . At low  $[O_2(^1\Delta)]$ , the scaling also seems to fail for  $[I^*]/[O_2(^1\Delta)]$ . Some of these deviations may reflect difficulties resulting from our addition of large amounts of He carrier with the  $I_2$ . Helium has a large effect on the system gasdynamics (Figure 24). A correction was applied for this effect in the data reduction program; however, in future experiments, Ar instead of He and a heated  $I_2$  saturator should be used to minimize the diluent added with the  $I_2$ . Nevertheless, most of the scaling problems result from a more serious source.

Not only does this system exhibit positive feedback, it also can manifest strong spatial inhomogeneities. Such inhomogeneities make kinetic analysis extremely difficult; however, it is easily shown that the centerline of a flow tube will always have the highest ratio of  $I^*/I$ . Thus, a laser device is possible in a system where the volume-averaged  $I^*/I$  ratio is not inverted.

Figure 24. Reduction of  $[O_2(^1\Delta)]$  with He +  $I_2$  Addition. (Straight line is gasdynamic effect of He alone.)

In Appendix B, the full steady-state expression for the  $[O_2(^1\Sigma)]$  is derived. This equation forcefully demonstrates the effect of inhomogeneous species concentrations

$$\frac{[O_2(^1\Sigma)]}{[O_2(^1\Sigma)]^0} = \frac{1 + k_2 k_1 [I] / k_9 (k_5 + k_6) [O_2(^3\Sigma)]}{1 + [(k_{15} + k_{16}) / k_{10}] [I_2]} \quad (B-12)$$

The second term in the denominator does not appear in the expression derived by Derwent and Thrush, Eq. (B-13), which is a special case for large  $[O_2(^1\Sigma)]$  and small  $[I_2]_{\text{added}}$ . In steady-state,  $I_2$  is only formed at the walls by heterogeneous recombination. As  $I_2$  molecules diffuse away from the walls, collisions with  $O_2(^1\Sigma)$  dissociate them. Conditions can be found for which  $I_2$  is confined very close to the walls, where  $O_2(^1\Sigma)$  will be deactivated in any case (in other words, the boundary conditions for the differential equations are the same). In this case, the flow-tube-averaged emission by  $O_2(^1\Sigma)$  obeys the relation given by Derwent and Thrush, and  $k_2$ , the  $O_2(^1\Delta) - I^*$  energy pooling rate, can be extracted from the plots of Eq. (B-13). What conditions are necessary for this plot to be valid? Primarily, one needs to make  $[O_2(^1\Sigma)] \gg [I_2]$  in a large fraction of flow-tube volume. The following conditions help achieve this inequality:

1. Large values of the  $[O_2(^1\Delta)]$ .
2. Small values of  $\gamma_{10}$  and  $\gamma_{18}$ , the wall deactivation and recombination coefficients of  $O_2(^1\Sigma)$  and I atoms, respectively.
3. High system pressures to cut down I-atom and  $O_2(^1\Sigma)$  diffusion to the wall and  $I_2$  diffusion away from the wall.

The breakdown of system scaling occurs when the rate of production of  $O_2(^1\Sigma)$  molecules in the gas phase can no longer dominate the rate of production of  $I_2$  molecules at the walls. The  $I_2$  molecules then penetrate further

into the gas phase before being dissociated. The conditions for which Eq. (B-13) must be replaced by Eq. (B-12) can be predicted:

$$\frac{k_2 k_1}{k_9(k_5 + k_6)} = 3.8 \times 10^3 \quad (42)$$

$$\frac{k_{15} + k_{16}}{k_{10}} = 1 \times 10^{12} \text{ cm}^3/\text{mol} \quad \dagger \quad (43)$$

Therefore, write the following expression:

$$\frac{[\text{O}_2(^1\Sigma)]}{[\text{O}_2(^1\Sigma)]^0} = \frac{1 + 3.8 \times 10^3 [I]/[\text{O}_2(^3\Sigma)]}{1 + 1 \times 10^{12} [\text{I}_2]} \quad (44)$$

If the term  $1 \times 10^{12} [\text{I}_2]$  approaches 1, deviations from Eq. (B-13) will be observed. For  $[\text{I}_2] \cong 3 \times 10^{-13} \text{ mole/cm}^3$  ( $\sim 10^{-5}$  Torr), a 30% deviation is predicted. In Figures 21 through 23, deviations occur for  $[\text{I}_2]_{\text{added}} \cong 1.5 \times 10^{-11} \text{ mole/cm}^3$ . Thus, if the  $\text{I}_2$  were uniformly distributed in the tube, only 2% of the added  $\text{I}_2$  would have to remain undissociated to explain the fall-off observed in the present experiments. In addition, the  $k_2$  values determined in our work decrease systematically as  $[\text{O}_2(^1\Sigma)]^0$  increases. Therefore, even in the "linear regions" of Figures 21 through 23, the term  $1 \times 10^{12} [\text{I}_2]$  is important. Our value of  $k_2 = 1.3 \times 10^{10} \text{ cm}^3/\text{mole-sec}$ , obtained at the highest value of  $[\text{O}_2(^1\Sigma)]^0$ , agrees well with Derwent and Thrush's value of  $k_2 = 1.6 \times 10^{10} \text{ cm}^3/\text{mole-sec}$ .

<sup>†</sup>  $k_{10}$  is calculated for a 2-cm-diameter tube,  $P = 2.5$  Torr, and  $\gamma_{10} = 0.01$ .

If it were possible to start with a large value of  $[O_2(^1\Sigma)]^0$ , it would be possible to reach a condition where

$$\frac{[O_2(^1\Sigma)]}{[O_2(^1\Sigma)]^0} = \frac{3.8 \times 10^3 [I]}{1 \times 10^{12} [I_2] [O_2(^3\Sigma)]} \quad (45)$$

This expression indicates that the fraction of  $I_2$  dissociated remains constant if the  $(^1\Sigma)$  remains constant. Thus,  $(^1\Sigma)/(^1\Sigma)^0$  could exhibit an extensive plateau region. This plateau will persist until a new  $I^*$  quenching mechanism causes a deviation from the equilibrium ( $k_1, k_5$ ).

After completing this semiquantitative analysis of the behavior of  $O_2(^1\Sigma)$ , the fraction of the  $[I_2]_{\text{added}}$  that will be dissociated as a function of radial position in the flow tube must be determined. If it is assumed that  $I_2$  is formed only by wall recombination and that it is dissociated only by  $O_2(^1\Sigma)$ , steady-state analysis (Appendix B) for the flow-tube averaged  $[I_2]$  yields

$$\frac{[I_2]}{[I_2]^0} = \frac{1}{1 + [(k_{15} + k_{16})/k_{18}] [O_2(^1\Sigma)]} \quad (B-15)$$

As noted earlier, the amount of undissociated  $I_2$  is inversely proportional to  $[O_2(^1\Sigma)]$ . The amount of  $I_2$  is also minimized by a small recombination coefficient,  $k_{18}$ , for I atoms:

$$k_{18} = \left( \frac{R^2 P}{8D_o} + \frac{2R}{\gamma_{18} \bar{u}} \right)^{-1} \quad (46)$$

where  $R$  is the tube radius,  $D_o$  is the diffusion coefficient of I atoms in 1 atm of  $O_2$  ( $\sim 0.2 \text{ cm}^2/\text{sec}$ ),  $P$  is the pressure in atmospheres, and  $\bar{u}$  is the radial velocity of  $[I]$  ( $\sim 1.5 \times 10^4 \text{ cm/sec}$ ). Figures 25 and 26 are representative

**Figure 25. Analytic Prediction of Fractional Dissociation of  $I_2$  by  $O_2(^1\Sigma)$ . Part I. Variation with Tube Radius (R) and I-Atom Wall Recombination Efficiency ( $\gamma_{18}$ ) for  $[O_2(^1\Sigma)]$  Typical of Microwave Discharge Conditions**

**Figure 26. Analytic Prediction of Fractional Dissociation of  $I_2$  by  $O_2(^1\Sigma)$ . Part II. Variation with Tube Radius ( $R$ ) and I-Atom Wall Recombination Efficiency for  $[O_2(^1\Sigma)]$  Typical of Low-Temperature  $O_3$  Photolysis**

plots of  $[I_2]/[I_2]^0$  versus  $\gamma_{18}$  for various values of R and  $[O_2(^1\Sigma)]$ . A linear region of the plots develops when the loss of I atoms is no longer diffusion controlled (i.e., when  $\gamma_{18}$  is small):

$$\frac{[I_2]}{[I_2]^0} \approx \frac{\gamma_{18}}{2k_{15}R[O_2(^1\Sigma)]}$$

Although to the author's knowledge, no one has actually measured  $\gamma_{18}$  on Halocarbon wax, Glass and coworkers have measured  $\gamma \leq 10^{-4}$  for Br atoms on this surface. They also found that pretreatment of the wax with  $F_2$  lowered  $\gamma$  substantially. It would appear that  $\gamma_{18}$  on Halocarbon wax is  $\approx 10^{-3}$ . This would mean that

$$\frac{[I_2]}{[I_2]^0} \approx 5 \times 10^{-14} [O_2(^1\Sigma)]^{-1}$$

in a 2-cm-diameter tube. Therefore, for  $[O_2(^1\Sigma)] = 5 \times 10^{-11}$  mole/cm<sup>3</sup> ( $\sim 1$  m Torr), only 0.1% of the  $I_2$  would remain undissociated. The highly deleterious effect of an efficiently recombinant surface for I atoms is shown in Figure 27. These are very realistic conditions for discharged  $O_2$  if it is assumed that  $\gamma_{18} = 1$  (which is likely for an uncoated surface). Even though 25% of the  $I_2$  remains undissociated, only 1% of the  $I_2$  is undissociated along the tube center, if the  $[O_2(^1\Sigma)]$  remains at  $4 \times 10^{12}$ /cm<sup>3</sup>.

#### 4. LOW-TEMPERATURE $O_3$ PHOTOLYSIS: $I^*$ AND $O_2(^1\Sigma)$ BEHAVIOR

An attempt was made to survey the following experimental conditions:

1.  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratios of  $\sim 0.2$  and low concentrations of added  $I_2$ .
2.  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratios of  $\sim 0.2$  and high concentrations of added  $I_2$ .
3. Maximized  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratio and low concentration of added  $I_2$ .

**Figure 27. Radial Distribution of  $I_2$  in 2-cm i.d. Flow Tube. Analytic Prediction of the  $I_2$  Fractional Dissociation For a Flow Tube with Efficient ( $\gamma_{I_2} = 1$ ) Wall Recombination of I Atoms. Experimental Conditions:  $PO_2 = 2.5$  Torr,  $[O_2(^1\Sigma)] = 4 \times 10^{12} \text{ cm}^{-3}$ ,  $([I_2]/[I_2]^0)_{Ar} = 0.25$**

The results for the first case are shown in Figure 28. The  $[I^*]/[I]$  ratios are  $\sim 0.5$ , i.e., inversion on the  $1.315 \mu\text{m}$  transition. The line (a) is not a fit to the data, but rather has a slope of 3.2, which is typical of the values obtained for  $K_{EQ}$  with the present apparatus. The slope of plot (b) gives a value of  $k_2 = 3.7 \times 10^{10} \text{ cm}^3/\text{mol-sec}$ . As with the discharged  $\text{O}_2$  data,  $k_2$  becomes larger as  $[\text{O}_2(^1\Sigma)]^0$  becomes smaller, the result of incomplete dissociation of  $\text{I}_2$ , which would produce an error in  $k_e$  in the observed direction. The value of  $[\text{O}_2(^1\Sigma)]^0$  for Figure 28 is  $1.0 \times 10^{-14} \text{ moles/cm}^3$ . Since the process

has a rate coefficient of  $1 \times 10^{14} \text{ cm}^3/\text{mol-sec}$  (Appendix C), the initial dissociation rate for  $\text{I}_2$ ,  $R^0$ , is  $1.0 \text{ sec}^{-1}$ , and the maximum rate is  $R^{\text{max}} = 20 \text{ to } 30 \text{ sec}^{-1} \{R = k_{15}[\text{O}_2(^1\Sigma)]\}$ . These rates are obviously very slow, as is the energy-pooling rate between  $\text{O}_2(^1\Delta)$  and  $\text{I}^*$ , which replenishes  $\text{O}_2(^1\Sigma)$ ,  $k_2[\text{O}_2(^1\Delta)] \cong 7.5 \text{ sec}^{-1}$  for an  $\text{O}_2(^1\Delta)$  pressure of 10 mTorr. Since the  $\text{I}_2$  mixing-to-observation time is 70 msec, it is unlikely that  $k_{15}$  provides the only mechanism for dissociating  $\text{I}_2$  in this system. For an  $\text{I}_2$  dissociation rate equal to  $R^0$ , less than 7% of the  $\text{I}_2$  will be dissociated. For an  $\text{I}_2$  dissociation rate equal to  $R^{\text{max}}$ , approximately 17% of the  $\text{I}_2$  remains undissociated at  $t = 70 \text{ msec}$ . Unfortunately, the time evolution of  $\text{I}^*$  and  $\text{O}_2(^1\Sigma)$  was not measured. Nevertheless, since  $[\text{O}_2(^1\Sigma)]^0 \approx 2 \times 10^{-7} \text{ Torr}$ ,  $[\text{O}(^3\text{P})]$  of  $10^{-5} \text{ Torr}$  would probably be more effective in producing the initial dissociation of  $\text{I}_2$  than is  $\text{O}_2(^1\Sigma)$ . Since those  $\text{O}(^3\text{P})$  atoms will be consumed, however, for  $\text{I}_2$  pressures of  $10^{-4}$  to  $10^{-3} \text{ Torr}$ , the bulk of the dissociation must be done by  $\text{O}_2(^1\Sigma)$ . The oxygen atoms only serve to initiate the process.

Figure 29 presents data for the second case, where relatively large amounts of  $\text{I}_2$  are added. It resembles Figure 28 for small  $\text{I}_2$  additions and

Figure 28. Behavior of  $I^*$  and  $O_2(^1\Sigma)$  in  $O_2^*$  Produced by  $O_2$  Photolysis. Part I.  $P_{O_3}^0 \approx 40$  mTorr,  $P_{O_2(^1\Delta)} \approx 9$  mTorr,  $P_{N_2} = 2.2$  Torr,  $[O_2(^1\Sigma)]^0 = 1 \times 10^{-14}$  moles/cm<sup>3</sup>. From line (a),  $K_{EQ} = 3.2$ ; whereas from line (b),  $k_2 = 3.7 \times 10^{10}$  cm<sup>3</sup>/mole-sec.  $[I^*]/[I] \approx 0.5$

Figure 29. Behavior of  $I^*$  and  $O_2(^1\Sigma)$  in  $O_2^*$  Produced by  $O_3$  Photolysis. Part II.  $P_{O_3} \approx 50$  m Torr,  $P_{O_2(^1\Delta)} \approx 10$  m Torr,  $P_{N_2} = 2.1$  Torr,  $[O_2(^1\Sigma)]^0 = 1.2 \times 10^{-14}$  moles/cm<sup>3</sup>. From line (a),  $K_{EQ} = 3.2$ ; whereas from line (b),  $k_2 = 4.1 \times 10^{10}$  cm<sup>3</sup>/mol-sec.  $[I^*]/[I] \approx 0.5$

then rapidly exhibits the  $O_2(^1\Sigma)$  catastrophe for  $I^*/O_2(^1\Delta)$  ratios  $\geq 1.2 \times 10^{-2}$ . Below that ratio,  $K_{EQ} = 3.2$  is obeyed, indicating that the  $I_2$  must be nearly dissociated. As in the discharged  $O_2$  case, the gasdynamic corrections are large as a result of the addition of He; thus, the data in region of large  $I_2$  addition are subject to sizable systematic errors. The use of a heated  $I_2$  saturator with Ar as a carrier gas would solve this problem.

For the third case, the optimized production of  $O_2(^1\Delta)/O_2(^3\Sigma)$  is presented in Appendix E as a sample calculation. If sufficiently small  $O_3$  concentrations are used,  $[I^*]/[I]$  ratios substantially greater than 0.5 can be achieved for very low  $[I_2]$  added. Figures 28 and 29 demonstrate that inversion in  $I^*$  is possible in the present apparatus only for  $[O_2(^1\Delta)] \leq 10\text{m Torr}$ .

## VI. CONCLUSIONS

The low-temperature  $O_3$  photolysis system has permitted us to verify that  $I^*/I$  ratios  $> 0.5$  can be produced by energy transfer from  $O_2(^1\Delta)$ . Thus, a cw energy-transfer iodine laser should be possible to construct. Two results that affect system scaling must be addressed in the future. The first result is from the LTOP experiments, where the initial rate of dissociation of injected  $I_2$  is much too rapid to be explained by the  $O_2(^1\Sigma)$  mechanism ( $k_{15}$ ). In the absence of  $I_2$ ,  $[O_2(^1\Sigma)] = 10^9 - 10^{10}/\text{cm}^3$ . Even the large dissociation rate of  $k_{15} = 2 \times 10^{-10} \text{ cm}^3/\text{mole-sec}$  gives an extremely slow dissociation time  $2 \times 10^{-10} \times 10^{10} = 2 \text{ sec}^{-1}$  or  $\tau_{\text{Diss}} \sim 0.5 \text{ sec}$ . Given the chemical simplicity of this system, the only other species that could be responsible for dissociating  $I_2$  are  $O_3$  and  $O(^3P)$ . This point really needs to be further clarified since the kinetic modelling cannot reproduce the observed behavior at present.

The second scaling problem that any method of  $O_2(^1\Delta)$  production will encounter is the problem of wall deactivation of  $O_2(^1\Sigma)$  and wall recombination of I atoms. Basically, the production rate of  $O_2(^1\Sigma)$  needs to be large enough to overcome the production rate of  $I_2$  at the walls. This problem can probably be solved with Halocarbon wax coatings. Furthermore, the  $O_2(^1\Sigma)$  in the presence of  $I_2$  must be large enough so that the  $I_2$  dissociation time  $\{k_{15}[O_2(^1\Sigma)] = \tau_{\text{Diss}}\}$  is much shorter than the diffusion time of  $I_2$  from the walls to the tube center. For small diameter systems ( $\sim 2 \text{ cm}$ ),  $[O_2(^1\Sigma)] \sim 10^{13}/\text{cm}^3$  will be needed.

The low-temperature photolysis method suffers from the low intensity of the present system. Two methods exist for scaling this method to larger cw production rates of  $O_2(^1\Delta)$ . The first is to use larger and more efficient cw lamps, which are, in fact, available. A less expensive test of the scaling of this method would be to attempt to run quasi-cw by flash photolyzing a sizable volume of  $O_3 + N_2 + SF_6$  and flowing the products through

the  $I_2$  mixing region. Given our present knowledge of the ability of the  $O_3$  photolysis system to produce high  $O_2(^1\Delta)/O_2(^3\Sigma)$  ratios, this would seem to be a reasonable near-term attempt to reach threshold densities of  $[I^*] - 1/2[I]$  while awaiting the development of a "clean" chemical generator of  $O_2(^1\Delta)$ .

## APPENDIX B

### ANALYTIC SOLUTIONS TO THE $O_2(^1\Delta)$ -I ATOM KINETIC EQUATIONS

#### A. STEADY-STATE CONCENTRATION OF $I^*$

$$\frac{-d[I^*]}{dt} = k_3[I^*] + k_2[I^*][O_2(^1\Delta)] + (k_5 + k_6)[I^*][O_2(^1\Delta)] + k_{11}[I^*] - k_1[I][O_2(^1\Delta)] \quad (B-1)$$

with  $d[I^*]/dt = 0$ ,

$$[I^*] = \frac{k_1[I][O_2(^1\Delta)]}{k_3 + k_2[O_2(^1\Delta)] + (k_5 + k_6)[O_2(^3\Sigma)] + k_{11}} \quad (B-2)$$

With the rate coefficients given in Appendix C, it can be shown that  $(k_5 + k_6)[O_2(^3\Sigma)]$  outweighs all other possible terms in the denominator. Thus,

$$\frac{[I^*]}{[I]} = \frac{k_1}{(k_5 + k_6)} \frac{[O_2(^1\Delta)]}{[O_2(^3\Sigma)]} \quad (B-3)$$

The rate coefficients  $k_1$  and  $k_5$  are related by an equilibrium constant defined by statistical mechanics. If  $k_6 \ll k_5$ , a very simple expression results, i.e.,

$$\frac{[I^*]}{[I]} = K_{EQ} \frac{[O_2(^1\Delta)]}{[O_2(^3\Sigma)]} \quad (B-4)$$

The term  $K_{EQ} = 2.88$  at  $T = 295$  K (see text).

## B. TIME DEPENDENCE OF $O_2(^1\Delta)$

$$\begin{aligned} \frac{-d[O_2(^1\Delta)]}{dt} = & (k_1 + k_7)[I][O_2(^1\Delta)] + k_2[I^*][O_2(^1\Delta)] + k_9[O_2(^1\Delta)]^2 \\ & - k_5[I^*][O_2(^3\Sigma)] - k_{10}[O_2(^1\Sigma)] \end{aligned} \quad (B-5)$$

Derwent and Thrush<sup>8</sup> found that  $-d[O_2(^1\Delta)]/dt$  is first order in both  $[I]$  and  $[O_2(^1\Delta)]$ . This eliminates the second, third, and last terms, all of which depend upon  $[O_2(^1\Delta)]^2$ . With those terms dropped and Eq. (B-3) substituted into (B-5)

$$\frac{-d[O_2(^1\Delta)]}{dt} = \frac{[(k_1 + k_7) - k_1 k_5]}{(k_5 + k_6)} [I][O_2(^1\Delta)] = \left\{ \frac{k_1 k_6}{(k_5 + k_6)} + k_7 \right\} [I][O_2(^1\Delta)] \quad (B-6)$$

Thus, a plot of  $\ln[O_2(^1\Delta)]$  versus  $t$  at constant  $[I]$  yields a value for  $k_1 k_6 / (k_5 + k_6) + k_7$ . Derwent and Thrush found this quantity to be  $(8 \pm 1) \times 10^{10} \text{ cm}^3/\text{mol-sec}$ . Using independently determined values for  $k_5$  and  $k_1$ , they were able to demonstrate the following inequalities:

$$k_6 = 4.4 \times 10^9 k_3 - \frac{k_3 k_7}{18} \leq 3.4 \times 10^{10} \text{ cm}^3/\text{mol-sec}$$

$$k_7 \leq 8 \times 10^{10} \text{ cm}^3/\text{mol-sec} \quad (B-7)$$

The branching ratio for  $I^*$  removal by electronic energy transfer ( $k_5$ ) versus quenching ( $k_6$ ) is

$$\frac{k_5}{k_6} \geq 470 \quad (B-8)$$

### C. STEADY-STATE DENSITY OF $O_2(^1\Sigma)$

In the absence of added  $I_2$ ,  $O_2(^1\Sigma)$  is formed by Process (A-9) [ $O_2(^1\Delta)$  energy pooling] and is deactivated at the flow tube walls (A-10). Under certain conditions, gas phase quenching (A-14) may become comparable to wall deactivation, but it will be ignored in this analysis.

The  $[O_2(^1\Sigma)]$  can be solved for in the absence of  $I_2$ .

$$[{}^1\Sigma]^0 = \frac{[{}^1\Delta]^2 k_9}{k_{10}} \quad (B-9)$$

When  $I_2$  is present

$$\frac{d[{}^1\Sigma]}{dt} = k_9[{}^1\Delta]^2 + k_2[I^*][{}^1\Delta] - (k_{15} + k_{16})[{}^1\Sigma][I_2] - k_{10}[{}^1\Sigma] = 0 \quad (B-10)$$

$$[{}^1\Sigma] = \frac{({}^1\Delta)^2 \left( k_9 + \left\{ k_2[I^*]/[{}^1\Delta] \right\} \right)}{k_{10} + (k_{15} + k_{16})[I_2]} \quad (B-11)$$

$$\frac{[{}^1\Sigma]}{[{}^1\Sigma]^0} = \frac{\left( \left[ 1 + k_2 k_1 / k_9 (k_5 + k_6) \right] \left\{ [I]/[O_2(^3\Sigma)] \right\} \right)}{1 + \left\{ (k_{15} + k_{16})[I_2] \right\} / k_{10}} \quad (B-12)$$

Under special circumstances discussed by Derwent and Thrush and in Section V.B.3 of this report, the above expression may be approximated as

$$\frac{[{}^1\Sigma]}{[{}^1\Sigma]^0} - 1 = \frac{k_2 k_1}{k_9 (k_5 + k_6)} \frac{[I]}{[O_2(^3\Sigma)]} \quad (B-13)$$

# D. STEADY-STATE DENSITY OF $I_2$

$$\frac{-d[I_2]}{dt} = (k_{15} + k_{16})[I_2][O_2(^1\Sigma)] - \frac{k_{18}}{2} ([I] + [I^*]) = 0 \quad (B-14)$$

Since  $[I_2]^0 - [I_2] = 1/2([I^*] + [I])$ , by suitable arrangement,

$$\frac{[I_2]}{[I_2]^0} = \frac{1}{1 + [(k_{15} + k_{16})/k_{18}][O_2(^1\Sigma)]} \quad (B-15)$$

is obtained.

## SAMPLE CALCULATION FOR PRODUCTION OF POPULATION INVERSION IN I ATOM

### A. DISCHARGED O<sub>2</sub> CALIBRATION

1. Dimol sensitivity constant =  $1.8 \times 10^6 \text{ Hz-Torr}^{-2}$
2. Experimental conditions:  $P_{O_2} = 2.472 \text{ Torr}$ ;  $\dot{m}_{O_2} = 4.75 \text{ L-Torr/sec}$ ;  $I_{6340} = 5^2 \times 10^4 \text{ Hz}$ ;  $P_{1\Delta} = 0.167 \text{ Torr}$ ;  $P_{3\Sigma} = 2.305 \text{ Torr}$ .
3.  $O_2(1\Delta)/O_2(3\Sigma) = 0.0725$ ; thus,  $I^*/I$  (predicted) =  $2.9(0.0725) = 0.21$ .
4. Calibration of Ge detector for  $O_2(1\Delta)$  at  $1.27 \mu\text{m} = 55 \text{ mTorr/mV}$ .

### B. I<sub>2</sub> ADDITION TO DISCHARGED O<sub>2</sub>

1.  $\dot{m}_{He + I_2} = 0.122 \text{ L-Torr/sec}$
2.  $P_{He + I_2} = 0.0625 \text{ Torr}$
3. Mole fraction of  $I_2$  in He at  $T = 298 \text{ K} = 3.1 \times 10^{-4}$
4.  $P_{I_2} = 1/2 (P_I + I^*) = 1.95 \times 10^{-5} \text{ Torr}$
5.  $I_{1.27}/I_{1.315} = 0.836$  with Eq. (21) used;  $I^*/1\Delta = 3.36 \times 10^{-5}$
6.  $P_{I^*} = 5.5 \times 10^{-6} \text{ Torr}$ ;  $P_I = 3.35 \times 10^{-5} \text{ Torr}$
7.  $I^*/I$  (measured)  $\approx 0.17$

### C. I<sub>2</sub> ADDITION TO PHOTOLYZED O<sub>3</sub>

1. Experimental conditions: photolysis temperature =  $-28^\circ\text{C}$ ;  
 $\dot{m}_{N_2} = 1.375 \text{ L-Torr/sec}$ ;  $\dot{m}_{He + I_2} = 0.122 \text{ L-Torr/sec}$ ;  $P_{\text{total}} = 2.000 \text{ Torr}$ ;  $P_{He + I_2} = 0.163 \text{ Torr}$ ;  $P_{I + I^*} = 1.02 \times 10^{-4} \text{ Torr}$ ;  
 $P_{N_2} = 1.804 \text{ Torr}$ ;  $P_{O_2} (\equiv 3/2 P_{O_3}) = 0.033 \text{ Torr}$ .

2.  $I_{6340} = 125 \text{ Hz} \rightarrow 8.3 \text{ mTorr O}_2(^1\Delta)$

$I_{1.27} = 120 \mu\text{V} \rightarrow 6.6 \text{ mTorr O}_2(^1\Delta)$

3.  $P_{\text{O}_2(^1\Delta)} \approx 7.5 \text{ mTorr}$

$P_{\text{O}_2(^3\Sigma)} \approx 25.5 \text{ mTorr}$

$\text{O}_2(^1\Delta)/\text{O}_2(^3\Sigma) = 0.29$

$I^*/I (\text{predicted}) = (2.9)(0.29) = 0.86$

$I_{1.27}/I_{1.315} = 4.7 \times 10^{-3}$

Using Eq. (21),  $I^*/\text{O}_2(^1\Delta) = 6.0 \times 10^{-3}$

$P_I^* = 4.5 \times 10^{-5} \text{ Torr}$

$P_I = 5.7 \times 10^{-5} \text{ Torr}$

$I^*/I (\text{measured}) = 0.79$

## THE IVAN A. GETTING LABORATORIES

The Laboratory Operations of The Aerospace Corporation is conducting experimental and theoretical investigations necessary for the evaluation and application of scientific advances to new military concepts and systems. Versatility and flexibility have been developed to a high degree by the laboratory personnel in dealing with the many problems encountered in the nation's rapidly developing space and missile systems. Expertise in the latest scientific developments is vital to the accomplishment of tasks related to these problems. The laboratories that contribute to this research are:

**Aerophysics Laboratory:** Launch and reentry aerodynamics, heat transfer, reentry physics, chemical kinetics, structural mechanics, flight dynamics, atmospheric pollution, and high-power gas lasers.

**Chemistry and Physics Laboratory:** Atmospheric reactions and atmospheric optics, chemical reactions in polluted atmospheres, chemical reactions of excited species in rocket plumes, chemical thermodynamics, plasma and laser-induced reactions, laser chemistry, propulsion chemistry, space vacuum and radiation effects on materials, lubrication and surface phenomena, photo-sensitive materials and sensors, high precision laser ranging, and the application of physics and chemistry to problems of law enforcement and biomedicine.

**Electronics Research Laboratory:** Electromagnetic theory, devices, and propagation phenomena, including plasma electromagnetics; quantum electronics, lasers, and electro-optics; communication sciences, applied electronics, semiconducting, superconducting, and crystal device physics, optical and acoustical imaging; atmospheric pollution; millimeter wave and far-infrared technology.

**Materials Sciences Laboratory:** Development of new materials; metal matrix composites and new forms of carbon; test and evaluation of graphite and ceramics in reentry; spacecraft materials and electronic components in nuclear weapons environment; application of fracture mechanics to stress corrosion and fatigue-induced fractures in structural metals.

**Space Sciences Laboratory:** Atmospheric and ionospheric physics, radiation from the atmosphere, density and composition of the atmosphere, aurorae and airglow; magnetospheric physics, cosmic rays, generation and propagation of plasma waves in the magnetosphere; solar physics, studies of solar magnetic fields; space astronomy, x-ray astronomy; the effects of nuclear explosions, magnetic storms, and solar activity on the earth's atmosphere, ionosphere, and magnetosphere; the effects of optical, electromagnetic, and particulate radiations in space on space systems.

THE AEROSPACE CORPORATION  
El Segundo, California
